Preserved endothelium-dependent dilatation of the coronary microvasculature at the early phase of diabetes mellitus despite the increased oxidative stress and depressed cardiac mechanical function *ex vivo*

Evangelia Mourmoura^{1,2*}, Guillaume Vial^{1,2}, Brigitte Laillet³, Jean-Paul Rigaudière³, Isabelle Hininger-Favier^{1,2}, Hervé Dubouchaud^{1,2}, Beatrice Morio³ and Luc Demaison^{1,2,3}

Abstract

Background: There has been accumulating evidence associating diabetes mellitus and cardiovascular dysfunctions. However, most of the studies are focused on the late stages of diabetes and on the function of large arteries. This study aimed at characterizing the effects of the early phase of diabetes mellitus on the cardiac and vascular function with focus on the intact coronary microvasculature and the oxidative stress involved.

Materials and methods: Zucker diabetic fatty rats and their lean littermates fed with standard diet A04 (Safe) were studied at the 11th week of age. Biochemical parameters such as glucose, insulin and triglycerides levels as well as their oxidative stress status were measured. Their hearts were perfused *ex vivo* according to Langendorff and their cardiac activity and coronary microvascular reactivity were evaluated.

Results: Zucker fatty rats already exhibited a diabetic state at this age as demonstrated by the elevated levels of plasma glucose, insulin, glycated hemoglobin and triglycerides. The *ex vivo* perfusion of their hearts revealed a decreased cardiac mechanical function and coronary flow. This was accompanied by an increase in the overall oxidative stress of the organs. However, estimation of the active form of endothelial nitric oxide synthase and coronary reactivity indicated a preserved function of the coronary microvessels at this phase of the disease. Diabetes affected also the cardiac membrane phospholipid fatty acid composition by increasing the arachidonic acid and n-3 polyunsaturated fatty acids levels.

Conclusions: The presence of diabetes, even at its beginning, significantly increased the overall oxidative stress of the organs resulting to decreased cardiac mechanical activity *ex vivo*. However, adaptations were adopted at this early phase of the disease regarding the preserved coronary microvascular reactivity and the associated cardiac phospholipid composition in order to provide a certain protection to the heart.

Background

The prevalence of Type 2 Diabetes (T2D) is increasing at an alarming rate assuming epidemic dimensions in industrialized societies [1]. Individuals with T2D have increased risk for developing cardiovascular diseases (CVDs), which is the main cause of early mortality and morbidity in the Western world [2]. Insulin resistance and T2D usually result from excess intake of deleterious nutrients such as saturated and trans fatty acids [3]. Consequent metabolic changes such as hyperinsulinemia and hyperglycemia [4] can provoke vascular lesions and endothelial dysfunctions at both micro- and macro-circulations [5-8]. The vulnerability of the coronary circulation to the diabetic milieu can lead to endothelial dysfunction at this bed, which consists a significant biomarker of early coronary artery disease independently of atherosclerosis [9].

An accurate experimental model in order to clarify the mechanisms responsible for the pathophysiology of diabetes evolution and its complications is the inbred Zucker diabetic fatty (ZDF) rat. The homozygous *fa/fa* Zucker rat exhibits hyperphagia caused by a non-functioning leptin receptor. This leads to the development of obesity, hyperglycemia, hyperinsulinemia and finally diabetes at a young age [10,11]. Previous studies on these rats in the later stages of diabetes have demonstrated that chronic hyperglycemia and hyperlipidemia can result in inflammation [12,13], increased oxidative stress and vascular dysfunction [14,15]. Coppey *et al.* [16] have shown that the endothelium-mediated responses to acetylcholine (ACh) are attenuated in epineurial arterioles of the sciatic nerve in diabetic ZDF rats. A key feature is the reduced production of nitric oxide (NO), a compound which mediates endothelium-dependent vasorelaxation and inhibits inflammation. In T2D, its bioavailability can be diminished either by the impaired insulin signaling either by the action of reactive oxygen species (ROS) [17].

Although the consequences of the later stages of T2D on the cardiac and endothelial function are well characterized, less is known concerning the early period of the disease where an interventional treatment may be more effective. Furthermore, most studies are focused on the endothelial function and perfusion of large arteries [18-20] and few on the coronary function of resistance vessels. The primary function of the coronary microcirculation is to optimize nutrient and oxygen supply to the heart in response to any metabolic demand by coordinating the resistances within different microvascular domains, each governed by distinct regulatory mechanisms [21]. Coronary resistance arteries are capable of adapting to acute or chronic increases in blood flow leading to an increased NO-mediated relaxation and a consequent enlargement of their diameter. Furthermore,

endothelial dysfunction in resistance arteries seems to precede that of large arteries [22]. Although there is strong evidence indicating that T2D is associated with impaired vasodilator responses of both peripheral and coronary vessels, Oltman *et al.* [22] have demonstrated that in diabetic young (8- to 12 wk old) ZDF rats the coronary arteriolar dilation to ACh of isolated microvessels is preserved. However, these *in vitro* studies isolate the coronary system from the cardiac environment and its influences.

Thus, this work aimed at studying the *ex vivo* cardiac and coronary vascular functions of young ZDF rats and at characterizing the levels of oxidative stress in their organs. The endothelial function of the intact coronary microvasculature was assessed in terms of endothelium-dependent and -independent vasodilatations in an *ex vivo* heart perfusion model at this phase of T2D. The NO production in aortas and hearts was evaluated indirectly by estimating the degree of phosphorylation of the endothelial NO-synthase (eNOS) at serine 1177 (Ser1177) and the iNOS levels in the heart. Finally, the fatty acid profile of cardiac membrane phospholipids was evaluated since any modification at this level leads to functional changes in lipid-protein interactions and related signaling pathways.

Methods

Animals and experimental design

All experiments followed the European Union recommendations concerning the care and use of laboratory animals for experimental and scientific purposes. All animal work was approved by the local board of ethics for animal experimentation (Cometh) and notified to the research animal facility of our laboratory (authorization n° 38 07 23). The performed research was in compliance with the ARRIVE guidelines on animal research [23].

Ten ZDF and eleven Zucker lean (ZL) male rats were obtained from Charles Rivers (L'Arbresle, France) at 7 weeks (wk) of age. Rats were housed in a temperature- and humidity-controlled facility on a 12-h light:dark cycle. The two groups were fed *ad libitum* with a standard carbohydrate diet (A04, Safe, Augy, France), they had free access to water and their body weight and food intake were recorded twice weekly. The composition of the chosen diet by weight is 60% assimilable glucides (52% mainly starch and cellulose), 16% proteins and 3% fat. After analysis of the fatty acid composition of our diet we found a formula with approximately 24% of saturated fatty acids (SFAs), 23% of monounsaturated fatty acids (MUFAs), 48% of n-6 polyunsaturated fatty acids (PUFAs) and 4.5% of n-3 PUFAs. Plasma glucose and glycated hemoglobin (HbA1c) concentrations were also measured weekly via the tail vein.

On the day of the experiment, the rats were weighed and heparinized (1500 I.U./kg) intraperitoneally 30 minutes (min) before their decapitation. Blood samples

were collected for further biochemical analysis and their retroperitoneal and mesenteric adipose tissues were weighed for determination of the abdominal fat mass [24]. Perfusion experiments were performed twice a day by alternating the rat phenotypes. The first experiment was performed between 8:00 a.m. and 8:30 a.m. and the second one between 12:30 p.m. and 1:00 p.m.

Cardiac function study

All rats underwent *ex vivo* Langendorff assessment of their cardiac function. For this reason, a rapid thoracotomy was performed and the heart was immediately collected in Krebs-Henseleit solution maintained at 4°C. It was then rapidly (less than one minute to avoid problems of cellular damages or preconditioning) perfused at constant pressure according to the Langendorff mode with a Krebs-Henseleit buffer containing (in mM) NaCl 119, MgSO₄ 1.2, KCl 4.8, NaHCO₃ 25, KH₂PO₄ 1.2, CaCl₂ 1.2 and glucose 11 mM as sole energy substrate. The perfusion buffer used was similar for both groups in order to minimize the variables studied. The buffer was maintained at 37°C and continuously oxygenated with carbogen (95% O₂/5% CO₂). A latex balloon connected to a pressure probe was inserted into the left ventricle and filled until the diastolic pressure reached a value of 7–8 mmHg. This allowed the monitoring of heart rate, systolic, diastolic and left ventricle developed pressures throughout the perfusion protocol. A pressure gauge inserted into the perfusion circuit just upstream the aortic cannula allowed the evaluation of the coronary pressure. The heart was perfused at constant pressure of 59 mmHg [25] for 30 minutes and the coronary flow for each heart was evaluated by weight determination of 1-min collected samples at the 25th min of perfusion. After this period, the heart was perfused at constant flow conditions, for which the flow rate was adjusted in order to obtain the same coronary flow as in the preparation at constant pressure. The systolic, diastolic and left ventricle developed pressures as well as the heart rate was determined after 10 min of perfusion at forced flow in order to allow a satisfying stabilization of the heart. The left ventricle developed pressure was calculated by subtracting the diastolic pressure to the systolic pressure. The rate-pressure product (RPP) was defined as the product of left ventricle developed pressure and heart rate and was used as indicator of the cardiac mechanical work [26]. All the parameters were recorded and analyzed with a computer using the HSE IsoHeart software (Hugo Sachs Elektronik, March-Hugstetten, Germany).

Coronary reactivity

After the evaluation of the cardiac function at constant flow, we assessed the effects of diabetes on the coronary reactivity. After the 10-min equilibration period at constant flow, the coronary tone was raised by using the

thromboxane analog U46619 (30nM), which was constantly infused into the perfusion system near the aortic cannula at a rate never exceeding 1.5% of the coronary flow. This allowed the obtainment of a coronary pressure between 120 and 130 mmHg. In our model of perfusion at forced flow, the aortic pressure equaled the coronary pressure and changes in the coronary tone triggered modifications of the aortic pressure. Changes in aortic perfusion pressure were thus used to monitor changes in coronary tone. Furthermore, this experimental model allows the evaluation of the coronary microvasculature reactivity since the coronary resistance vessels determine the overall coronary pressure. Relaxation responses to Ach (4, 10, 20, 40, 60, 80 and 100 pmoles) and sodium nitroprusside (SNP, 100, 200, 400, 600, 800 and 1000 pmoles) injections were determined reflecting the endothelial-dependent vasodilatation (EDD) and endothelium-independent vasodilatation (EID) respectively.

The dilatation amplitude was calculated as the ratio between the maximal decrease in the coronary pressure and the coronary pressure just before the injection of the dilatation agents. Since the heart weight and coronary volume were subjected to intra- and inter-group variations, a correction was performed to normalise the input-function of the vasodilatation agents according to the coronary flow. The dose-response curve between the amount of vasodilatation agent injected and the maximal vasodilatation was then fitted to a logarithm function for each heart which allowed the fulfillment of statistical analyses. Moreover, the vasodilatation activity of the endothelial cells was also estimated from the corrected EDD and EID curves. For each heart and each injected Ach dose, the amount of SNP (reflecting the amount of vasodilator agents) necessary to obtain the same percentage of Ach-induced vasodilatation was extracted from the EID curve according to the formula: endothelial cell vasodilatation activity (ECVA) = $e^{[(\% \text{ Ach-induced dilatation} - b)/a]}$, where a and b are the coefficients of the theoretical EID curve. The results were expressed in pmole equivalents of nitroprusside. At the end of the perfusion protocol, the hearts were freeze-clamped and stored at -80°C until the biochemical analyses were performed.

Oxidative stress measurements

Plasma oxidative stress

Protein oxidation in the plasma was evaluated by the disappearance of protein thiol groups [27]. Plasma thiols were assayed in 20 µl of plasma, using 5,5'-dithiobis(2-nitrobenzoic acid (DTNB)) for deriving the thiol groups. The calibration curve was obtained by mixing two stock solutions of N-acetyl cystein (NAC) in the range of 0.125–0.6 mmol/l. Standards and plasma samples were measured spectrophotometrically at 415 nm (Hitachi 912,

B Braun Science Tec, France) in the presence of a phosphate buffer 50 mM, EDTA 100 mM, pH 8 and bis-5,5'-dithio-bis(2-nitrobenzoic acid) 10 mM.

The antioxidant status of the plasma was evaluated using ferric reducing antioxidant power (FRAP) assay as a global marker of the antioxidant power. The FRAP assay uses antioxidants as reductants in a redox-linked colorimetric method. In this assay, at low pH, a ferric-tripyridyltriazine (Fe^{III} -TPTZ) complex is reduced to the ferrous form, which is blue and monitored by measuring the change in absorption at 593 nm. The change in absorbance is directly proportional to the reducing power of the electron-donating antioxidants present in plasma. The absorbance change is translated into a FRAP value (in $\mu\text{mol/l}$) by relating the change of absorbance at 593 nm of test sample to that of a standard solution of known FRAP value.

Glutathione peroxidase (GPx) activity, which is a seleno-enzyme involved in protection against hydrogen peroxide (H_2O_2) was evaluated in plasma samples by the modified method of Gunzler [28] using tertbutyl hydroperoxide (Sigma Chemical Co, Via Coger, Paris, France) as a substrate instead of hydrogen peroxide. The principle of the assay is based on the coupled reaction with glutathione reductase (GR). Oxidized glutathione (GSSG), produced upon reduction of an organic hydroperoxide by GPx with glutathione (GSH) as electron donor, is recycled to its reduced state by GR and NADPH. The oxidation of NADPH to NADP^+ is accompanied by a decrease in absorbance at 340 nm. The rate of decrease in the A340 is directly proportional to the GPx activity in the sample. The assay was performed at 25°C and pH 7.0 that allowed a stable concentration of GSH in the reaction medium.

Cardiac oxidative stress

Lactate and pyruvate released in the coronary effluents were spectrophotometrically assayed according to Bergmeyer [29]. The lactate to pyruvate ratio was calculated to estimate the cytosolic redox potential (NADH/NAD^+) [30-32]. This is a highly specific assay using the enzyme lactate dehydrogenase (LDH) to catalyze the reversible reaction of pyruvate and NADH to lactate and NAD^+ . The catalytic action of LDH permits spectrophotometric measurement at 340 nm (spectrophotometer ULTROSPECTM 2100 pro, Amersham Biosciences, Uppsala, Sweden) of lactate production in terms of the generation of NADH in the reaction shown above. To measure lactate, the reaction is carried out from right to left with excess NAD^+ . To force the reaction to completion in this direction, it is necessary to trap formed pyruvate with hydrazine. The increased absorbance at 340 nm due to NADH formation becomes a mole-to-mole measure of the lactate originally present in the sample.

Lipid peroxidation was assessed by measuring the concentration of thiobarbituric acid reactive substances (TBARS) in cardiac homogenates [33]. TBARS were determined using the fluorimetric determination of malondialdehyde – thiobarbituric acid complex after acid hydrolysis at 95°C and extraction with n-butanol. Briefly, tissue homogenate aliquots were placed in polyethylene tubes mixed with TBA (thiobarbituric acid)/perchloric acid 7% (2:1, v/v) and incubated at 95°C. After cooling, n-butanol was added for the extraction and then the aliquots were centrifuged for 10 min at 35000 g. The supernatant was used to read the fluorescence at excitation and emission wavelengths of 532 and 553 nm respectively. The TBARS calculated were normalized to the content of polyunsaturated fatty acids of cardiac membrane phospholipids since it differed between groups. The protein thiol groups and FRAP assays were also evaluated in cardiac homogenates as described previously for the plasma.

Cardiac mitochondrial oxidative stress

The ratio between the activities of aconitase and fumarase of the myocardium was calculated as an indicator of mitochondrial ROS production. Mitochondrial aconitase is sensitive to inactivation by superoxide due to the susceptibility of its iron-sulfur core to oxidation; however, fumarase is unaffected. Thus, the activity ratio of aconitase to fumarase was calculated as an indicator of the presence of mitochondrial ROS [34]. Aconitase and fumarase activities were determined according to Gardner *et al.* [34], but were measured after extraction with a medium supplemented with citrate sodium (1 M) in order to stabilize the aconitase activity *ex vivo*. Values of aconitase and fumarase activities were determined on the same extract for each biological sample.

Respiratory chain complexes and citrate synthase activities

Activities of the NADH-ubiquinone oxido-reductase (complex I), succinate-ubiquinone oxido-reductase (complex II), ubiquinol cytochrome c reductase (complex III), cytochrome c oxidase (complex IV), NADH cytochrome c reductase (activity of complex I + III) and succinate cytochrome c reductase (activity of complex II + III) were determined as previously described [35]. Heart samples (100 mg) were homogenized at 4°C with 0.9 ml of a potassium phosphate buffer 100 mM, pH 7.4. The homogenates were centrifuged (1,500 × g, 5 min, 4°C), and the resulting supernatants were stored at -80°C until the determination of the various enzymatic activities. Activity of the citrate synthase was determined according to Faloona and Srere [36]. The activities of the respiratory chain complexes and citrate synthase were expressed in units per mg of proteins.

Western blot

The expressions of total eNOS, phosphorylated eNOS at Ser1177 and iNOS were evaluated by Western blot. Frozen samples were homogenized in ice-cold lysis buffer containing 20 mM Tris (pH 7.8), 137 mM NaCl, 2.7 mM KCl, 1 mM MgCl₂, 1% Triton X-100, 10% (w/v) glycerol, 10 mM NaF, 1 mM ethylenediaminetetraacetic acid, 5 mM Na pyrophosphate, 0.5 mM Na₃VO₄, 1 µg/ml leupeptin, 0.2 mM phenylmethylsulfonyl fluoride and 1 mM benzamidine. The homogenates were centrifuged at 5,000 *g* for 20 min at 4°C, and the protein concentration in the supernatant was determined in each aliquot. Protein extracts (50 µg/lane) were loaded onto a 10% SDS gel and separated by electrophoresis. Extracts from the control group were loaded on both gels, and the amount of protein was accordingly compared pairwise. Proteins were transferred to nitrocellulose membranes. The membranes were incubated overnight at 4°C with rabbit antibodies against total eNOS (1:150, ThermoScientific, Illkirch, France), iNOS (1:1,000, BD Biosciences Pharmingen, Le Pont de Claix, France) and phosphospecific mouse antibodies against eNOS Ser1177 (1:1,000, BD Biosciences Pharmingen, Le Pont de Claix, France). After being washed in tris buffered saline (TBS)-Tween, the membranes were incubated with horseradish peroxidase-conjugated anti-mouse IgG for eNOS Ser1177 (1:3000, Jackson ImmunoResearch, Montluçon, France) and anti-rabbit IgG for total eNOS and iNOS (1:20000, Jackson ImmunoResearch, Montluçon, France) for 1 h at room temperature, followed by additional washing. Proteins were visualized by enhanced chemiluminescence with ECL advanced Western blotting detection kit (Amersham Biosciences, Brumath, France) and quantified using densitometry and Image J software. PAN-Actin (1:1000, Cell Signaling Technology, St-Quentin-en-Yvelines, France) was used as a loading control.

RNA isolation

Total RNA from rat hearts was isolated by using Tri reagent according to instruction recommended by the manufacturer. Briefly, 50 mg of tissue was homogenized in 1 ml of Tri reagent (Sigma Chemical Co, Via Coger, Paris, France) and the aqueous phase was collected after chloroform addition. RNA was precipitated with isopropanol and washed with 75% ethanol. The RNA pellet was dried and redissolved in diethylpyrocarbonate water. The concentration and purity of RNA were determined by measurement of absorbance at 260:280 nm. RNA samples (2.5 µg of total RNA) were analyzed by 1% agarose electrophoresis for control of RNA degradation.

Quantitative real-time PCR

1 µg of total RNA of each sample was primed with oligo (dT) and reverse transcribed with SuperscriptIII reverse

transcriptase (RT) (Life Technologies SAS, Saint Aubin, France) to produce cDNA. PCR amplification of the cDNA from the reverse transcription reaction was carried out using specific primer pairs for *Nos2* (nitric oxide synthase 2, inducible; GenBank accession number: NM_012611) and the house-keeping gene *Arbp* (acidic ribosomal phosphoprotein; GenBank accession number: NM_022402.2). Sequences of the primers for analysis of mRNA were for *Nos2* (forward): CAG GTT GAG GAT TAC TTC TTC CA; *Nos2* (reverse): TGT CAG AGT CTT GTG CCT TTG with PCR product length of 132 bp and for *Arbp* (forward): CCT GCA CAC TCG CTT CCT A; *Arbp* (reverse): TGA TGG AGT GAG GCA CTG AG with PCR product length of 95 bp (Eurogentec France SASU, Angers, France). These primers were intron-spanning in order to avoid genomic DNA contamination. Quantitative real-time PCR (qRT-PCR) was then performed with a LightCycler FastStart DNA Master SYBR Green I kit (Roche, Diagnostics, Meylan, France) on a LightCycler 1.5 Instrument (Roche, Diagnostics, Meylan, France) in capillaries of 20 µl volume/capillary by adding 4 µl of Master Mix solution, 0.5 µM of *Nos2* or 0.4 µM *Arbp* primers, 5 µl of the sample and completing up to 20 µl with RNase free water. The assays were performed in duplicates. The capillaries were then appropriately sealed, centrifuged for few seconds at high speed and then placed into the LightCycler. The thermal cycle conditions were 95°C for 10 min (pre-incubation) followed by 45 cycles of amplification that were run at 95°C for 10 s, at 55°C for 10 s and at 72°C for 10 s for *Nos2* and at 95°C for 10 s, at 55°C for 5 s and at 72°C for 6 s for *Arbp*. Cycle threshold values (Ct) were analyzed and the level of expression of *Nos2* gene was standardized against that of *Arbp* gene detected in the same sample by using the $2^{-\Delta\Delta C_t}$ method [37].

Fatty acid composition of cardiac phospholipids

The phospholipid fatty acid composition was determined in cardiac homogenates as previously described [38]. The lipids were extracted according to Folch *et al.* [39]. The phospholipids were separated from non-phosphorus lipids using a Sep-pack cartridge [40]. After transmethylolation, the fatty acid methyl esters were separated and analyzed by gas chromatography.

Other biochemical determinations

Blood glucose concentrations were determined with a glucose analyzer (ACCU-CHECK Active, Softclix). Plasma insulin concentrations were determined using a radioimmunoassay kit (ICN Pharmaceuticals, Orangeburg, SC). Plasma triglyceride and cholesterol levels were measured using commercially available kits from Biomérieux (Craponne, France) and Roche (Boulogne-Billancourt,

France), respectively. HbA1c levels were evaluated with the kit Bayer Healthcare's analyser A1cNow[®] determined in blood samples (5 μ l) drawn from the rat fingers. Proteins were measured using the bicinchoninic acid method with a commercially available kit (Thermo Scientific, Rockford, IL).

Statistical analysis

Results are presented as mean \pm S.E.M. Animal weight, heart dry weight, glycemia, activity of respiratory chain complexes, aconitase-to-fumarase and lactate-to-pyruvate ratios and data describing the oxidative stress and the cardiac mechanical and vascular function (developed pressure, heart rate, rate pressure product, coronary pressure, and coronary flow) were contrasted across the two groups by one-way analysis of variance (ANOVA). Measures related to the action of the vasodilatation agents were treated with repeated-measures ANOVA to test the effect of the diabetes of ZDF rats (external factor), that of the amount of dilatation agent (internal factor) and

their interaction. When required, group means were contrasted with a Fisher's LSD test. A probability (p) less than 0.05 was considered significant. Statistical analysis was performed using the NCSS 2004 software.

Results

General data

As shown in Figure 1, the food intake was always higher in the ZDF compared to the ZL group (+85% at the 9th wk of age), which provoked their increased body weight (+21% at the day of the sacrifice). Consequently, based on the analysis of the diet ingredients, the ZDF group consumed greater amounts of fat than the lean group. The abdominal fat mass was partly responsible for the increased body weight since the mesenteric, retroperitoneal and visceral adipose tissues were significantly heavier as shown in Table 1. However, the heart weight of the ZDF rats did not differ of that of the ZL animals (Table 1).

Figure 2 shows that the blood glucose concentration of the ZDF rats was increased as soon as the 7th wk of

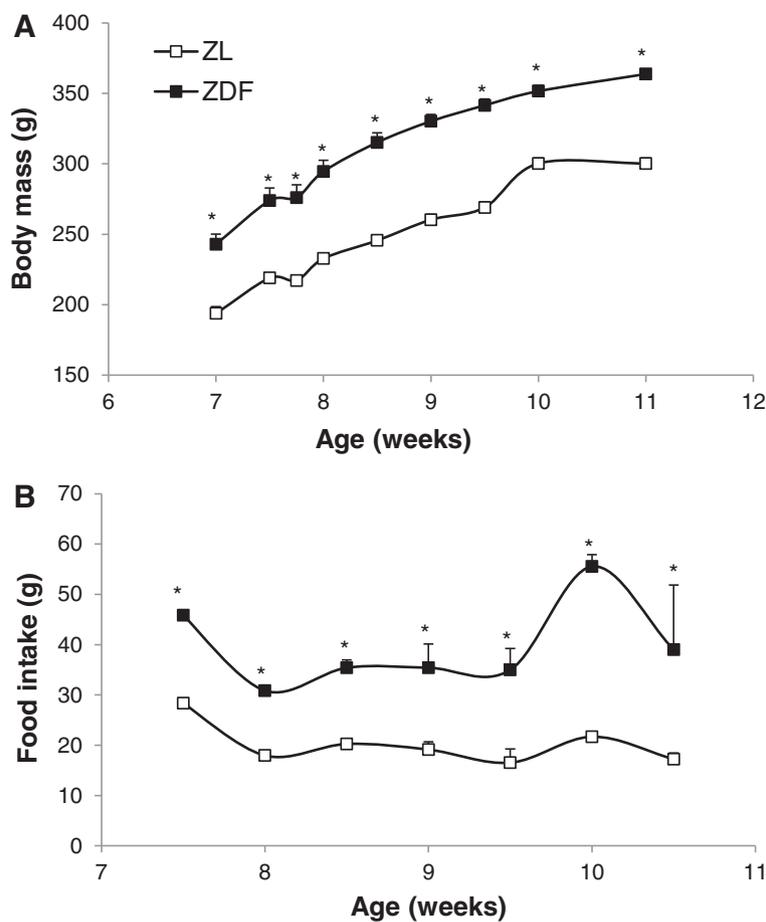

Figure 1 Evolution of the body weight and food intake of the animals. (A) Body weight and (B) Food intake of the animals between the 7th and 11th week of life. ZL: Zucker lean rats; ZDF: Zucker Diabetic Fatty rats. The number of experiments was 11 and 10 for the ZL and ZDF groups respectively. *: significantly different.

Table 1 Adipose tissue and heart weights

	ZL	ZDF
Mesenteric AT	1.77 ± 0.09	4.94 ± 0.22*
Retroperitoneal AT	1.04 ± 0.07	4.56 ± 0.13*
Visceral AT	2.81 ± 0.02	9.50 ± 0.32*
Abdominal AT	3.85 ± 0.22	14.06 ± 0.43*
Abdominal AT/BW	0.013 ± 0.001	0.039 ± 0.001*
Heart	203 ± 12	200 ± 6
Heart weight/BW (mg/g)	0.68 ± 0.03	0.55 ± 0.02*

The number of experiments was 11 and 10 for the ZL and ZDF groups respectively. The weight of mesenteric, retroperitoneal, visceral and abdominal adipose tissues is expressed in g of wet weight. The abdominal adipose tissue weight normalized to the body weight is expressed in g of wet weight per g of body weight. The heart weight is expressed in mg of dry weight. The heart-to-body weight ratio is expressed in mg of dry weight per g of body weight. ZL: Zucker lean rats; ZDF: Zucker diabetic fatty rats; AT: adipose tissue; BW: body weight; *: significantly different.

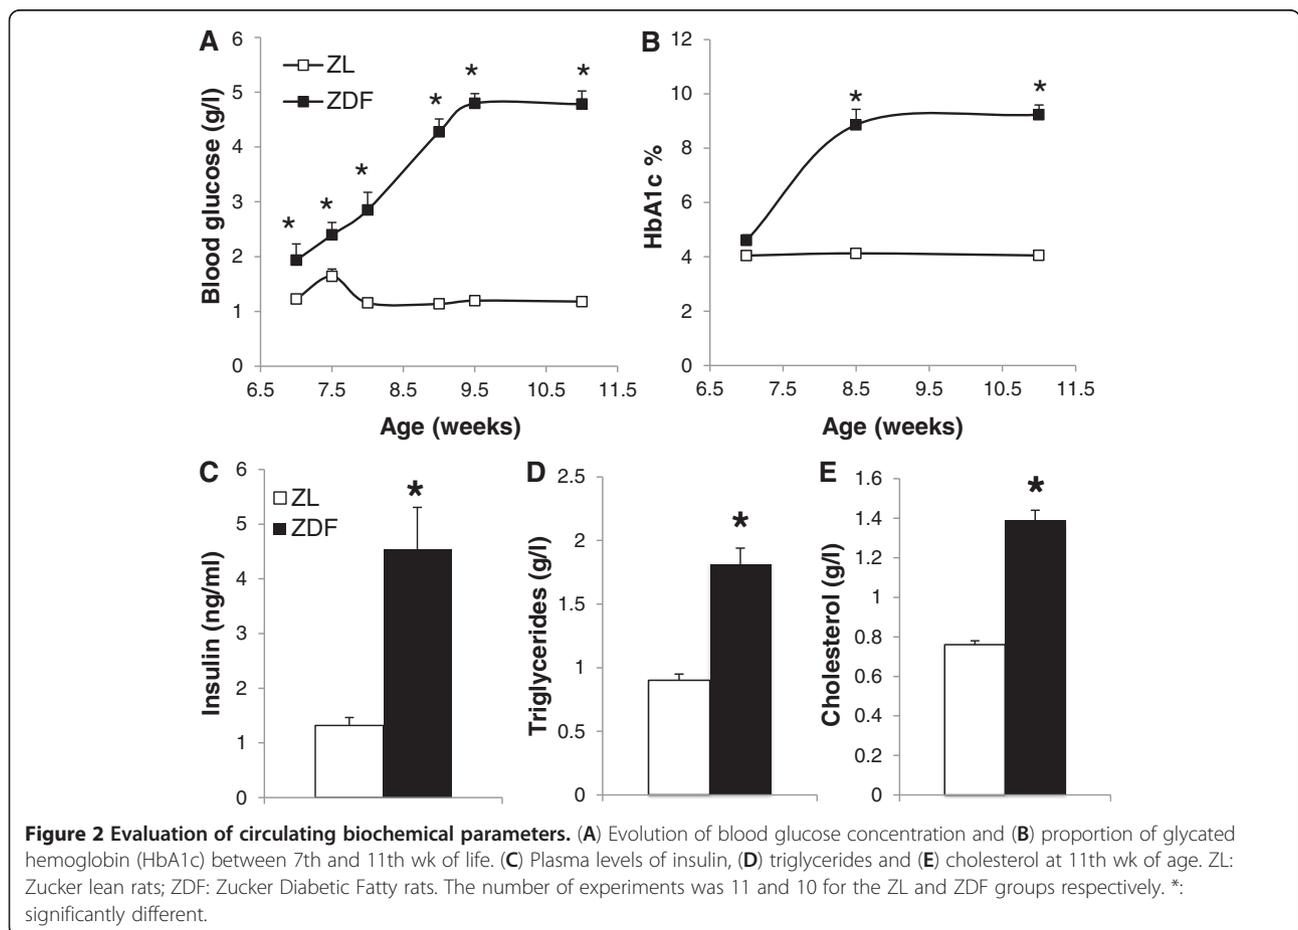

age and reached a value close to 5 g/l at the 9th wk (+276% compared to the ZL rats). The hyperglycemia triggered an increase in HbA1c already significant at the 9th wk (+56%) and a huge augmentation of the insulinemia (+244% at the moment of the sacrifice). The plasma triglyceride and cholesterol concentrations were

also significantly higher for the ZDF rats at the moment of the sacrifice.

Oxidative stress

The mitochondrial-derived oxidative stress was estimated in cardiac homogenates by the aconitase-to-fumarase ratio. As shown in Figure 3A, the ratio was significantly reduced in the ZDF group (-41%), indicating an increase in the cardiac mitochondrial oxidative stress. The lactate-to-pyruvate ratio in the coronary effluents (Figure 3B), reflecting the cytosolic redox potential, was also decreased in the ZDF group (-34%). This decrease in the cytosolic redox potential may indicate a diminished capacity of the system to buffer ROS and thus an increased presence of oxidizing species as its primary outcome [30-32]. In the heart, the global antioxidant power or the protein thiol groups were not modified by the diabetic state of the ZDF rats (Figure 4A). However, there was a significant increase of 105% in the lipid peroxidation as shown by the TBARS concentration normalized to the PUFAs content of the cardiac membrane phospholipids (Figure 4B).

In the plasma, even though the antioxidant enzyme GPx was significantly increased in the ZDF group

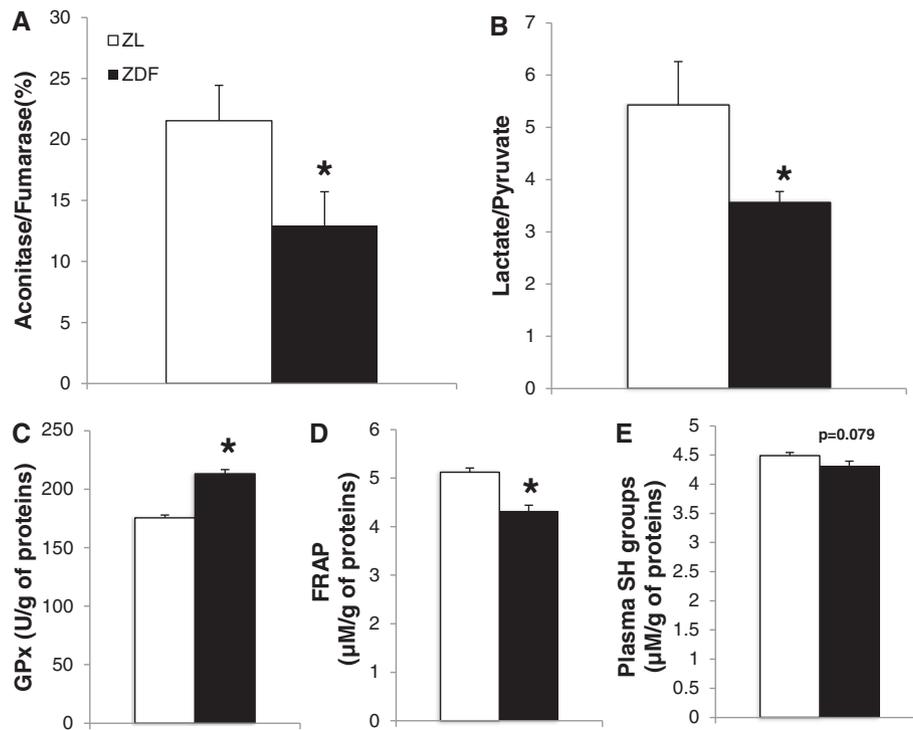

Figure 3 Oxidative stress measurements. (A) Mitochondrial oxidative stress estimated by aconitase-to-fumarase ratio. (B) Cytosolic oxidative stress estimated by lactate-to-pyruvate ratio. (C) Enzymatic activity of glutathione peroxidase (GPx) in the plasma. (D) Antioxidant power of the plasma estimated by the ferric reducing antioxidant power (FRAP) assay. (E) Systemic oxidative stress estimated by the disappearance of the plasma thiol (SH) groups. ZL: Zucker lean rats; ZDF: Zucker Diabetic Fatty rats. The number of experiments was 11 and 10 for the ZL and ZDF groups respectively. *: significantly different.

(+21.5%, Figure 3C), the global antioxidant power as estimated by the FRAP assay was significantly decreased (-15.6%, Figure 3D). This was accompanied by a decrease in the plasma thiol groups (Figure 3E), which however did not reach significance.

Mitochondrial enzymatic activities

Citrate synthase was significantly increased (+4.5%) in the ZDF group as shown by the values for the ZL versus the ZDF rats in Table 2. When normalized to the amount of myocardial proteins, the activity of the cytochrome oxidase was increased in the ZDF group (+20%). No modifications concerning the activities of the other respiratory chain complexes were observed.

Fatty acid composition of cardiac phospholipids

The fatty acid composition of cardiac membrane phospholipids was modulated by the development of diabetes (Table 3). The SFAs were significantly increased in the ZDF group (+24%), especially the 18:0 (+33%). This increase partly occurred at the detriment of the MUFAs. Indeed, all the MUFAs were reduced (-36, -27 and -42% for the 16:1n-7, 18:1n-9 and 18:1n-7, respectively). The n-6 PUFAs were also reduced, not only in their totality (-18%) but also regarding the 18:2n-6 (-52%). However,

the 20:3 n-6 and 20:4 n-6 were significantly increased (+152 and +47%, respectively). The important reduction of the n-6 PUFAs was accompanied by an increase in n-3 PUFAs (+98%). This was particularly true for the 22:5 n-3 and 22:6 n-3 levels (+130 and +97%, respectively). Finally, the n-6 to n-3 PUFA ratio of cardiac phospholipids was reduced by the occurrence of diabetes (-60%).

Cardiac function study

The results of the *ex vivo* cardiac function are shown in Table 4. The measured parameters were recorded when the heart was perfused at constant flow before the infusion of U46619. In the ZDF group, the RPP was reduced (-35%) compared to the ZL group. This was due to a reduction of the heart rate (-42%), since the left ventricle developed pressure was slightly increased (+18.2%). The changes in the RPP were consequently related to the observed decrease in coronary flow (-25%), but the coronary pressure was unaffected. The infusion of U46619 raised the coronary pressure from 80 mmHg to a value close to 125 mmHg in both groups.

Coronary reactivity

Figure 5A depicts an EDD, which was similar in the two groups, reaching 15% of dilatation as soon as 40 pmoles

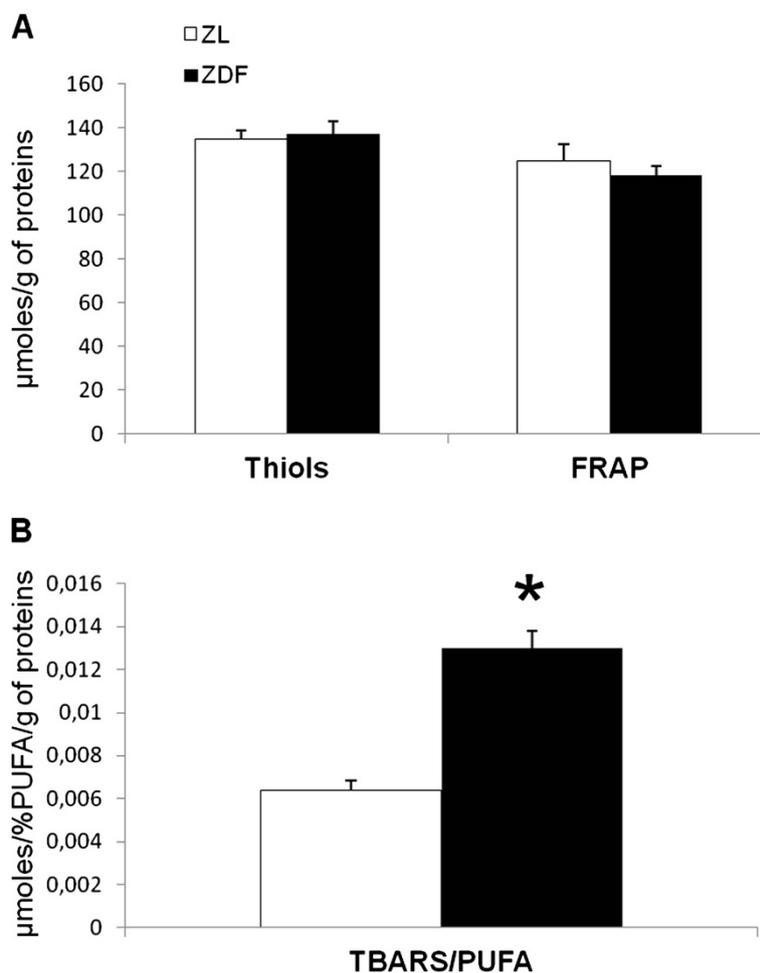

Figure 4 Oxidative stress in cardiac tissue. (A) Cardiac oxidative stress estimated by the disappearance of the protein thiol (SH) groups and the antioxidant power in cardiac homogenates by the ferric reducing antioxidant power (FRAP) assay. (B) Cardiac lipid peroxidation estimated by the thiobarbituric reducing substances (TBARS) assay normalized to the polyunsaturated fatty acid content of cardiac membrane phospholipids. ZL: Zucker lean rats; ZDF: Zucker Diabetic Fatty rats. The number of experiments was 11 and 10 for the ZL and ZDF groups respectively. *: significantly different.

The number of experiments was 11 and 10 for the ZL and ZDF groups respectively. ZL: Zucker lean rats; ZDF: Zucker Diabetic fatty rats; CI: NADH: ubiquinone oxidoreductase; CII: succinate-ubiquinone oxido-reductase; CIII: ubiquinol-cytochrome-c reductase; CIV: cytochrome c oxidase; CI + III: NADH cytochrome c reductase; CII + III: succinate cytochrome c reductase; CS: citrate synthase. The results are expressed in mU/mg of proteins. *: significantly different.

of Ach were injected. The EID was significantly increased in the ZDF group (Figure 5B) as soon as the SNP dose of 600 pmoles was injected (+14, +16 and +18% at the doses of 600, 800 and 1000 pmoles of SNP, respectively). Finally, the ECVA was not modified by the occurrence of diabetes (Figure 5C).

eNOS expression and phosphorylation

The eNOS expression and its phosphorylation at Ser1177 were evaluated in aortic and cardiac homogenates of both groups. No difference was observed between groups in the expression and phosphorylation of the enzyme neither in the aorta (Figures 6A and B) nor in the heart (Figures 6C and D).

Nos2 mRNA and protein expression

The *Nos2* mRNA and protein expression were evaluated in cardiac homogenates of both groups. No difference

was observed between groups at mRNA (Figure 7A) or protein level (Figure 7B).

Surprisingly, after using anti-iNOS antibody, a band of 95-kDa protein instead of 130 kDa was revealed. This could represent a breakdown product of iNOS but the harvest storage and analysis conditions were designed to minimize proteolysis. These experiments were repeated several times but the 130-kDa band never appeared which is consistent with findings by other authors that tried to detect iNOS in cardiac or skeletal muscle tissue [41,42]. It could thus be possible that this 95-kDa band could represent a novel isoform or an alternatively spliced form of iNOS as previously proposed [41]. Furthermore, the evaluation of its mRNA expression indicated the presence of *Nos2* mRNA in the samples and gave results that were in accordance with the Western blot findings.

Discussion

Even though several studies have examined the effects of diabetes on the vascular function, most of them used techniques of isolated vessels and most of them examined the late stages of diabetes [22,43]. This is the first study that focuses on the effects of T2D on the intact coronary microvasculature at the early phase of the disease. This study addressed cardiac mechanical function in an isolated heart model that provided also the opportunity to study the vascular functionality in the intact coronary circulation. This allowed the analysis of the coupling of cardiac and coronary function, which is not feasible in isolated vessels.

The ZDF rat has been well characterized as experimental model of T2D. The ZL rats in our study ate a normal amount of diet (approximately 20 g/day) and exhibited a low blood glucose concentration (1 g/l) and proportion of HbA1c (approximately 4%) between the 7th and 11th wk of life. Their insulinemia was also low (1 µg/l) at the moment of sacrifice. In contrast, the ZDF animals consumed greater amounts of food (more than 30 g/day) that resulted to a higher body weight during the whole course of the experiment. Their blood analysis revealed a glycemia reaching 5 g/l at the 9th wk of age and a proportion of HbA1c close to 9% representing an already established diabetic state. The insulinemia at the 11th week was almost 4 times higher than that of the ZL control animals, indicating functional β cells in the Langerhans islets despite the high blood glucose concentration. Furthermore, their plasma triglycerides and cholesterol levels were approximately 2 times higher than those of the lean animals. All these characteristics associated with the fact that the visceral fat mass was abnormally high, clearly demonstrate that the ZDF animals displayed a severe insulin resistance responsible for the development of type-2 diabetes, which corresponds to a stage of early human type 2 diabetes.

ZL: Zucker lean rats; ZDF: Zucker Diabetic Fatty rats; Ach: acetylcholine; SNP: sodium nitroprusside. The number of experiments was 11 and 10 for the ZL and ZDF groups respectively. *: significantly different.

In our study, the presence of diabetes provoked an enhanced cytosolic and mitochondrial oxidative stress in the hearts of the ZDF rats as observed by the lactate-to-pyruvate and aconitase-to-fumarase ratios respectively. It seems though that the respiratory chain complexes (RCC) were not implicated in the development of this mitochondrial oxidative stress, especially since the complex IV (CIV) activity was increased in the ZDF animals. It has been previously proposed that an up-regulation of CIV activity without any other changes in the other RCC or citrate synthase activities may serve to reduce any production of oxidative stress by the electron transport chain and improve the electron flux [44], but no measurements of mitochondrial respiration were performed in this study in order to directly evaluate the mitochondrial function that could be related to the observed depressed cardiac mechanical work. However, it is probable that a lack of mitochondrial antioxidant defenses could result to the increased mitochondrial oxidative stress observed in this study. The increased oxidative stress was also demonstrated in cardiac level by the TBARS results as already shown in the literature [22]. This could have been the result of the observed increase

in the n-3 PUFA content of the cardiac membrane phospholipids of the ZDF hearts, since n-3 PUFAs are highly susceptible to peroxidation. A hyperglycemia-induced ROS production could have resulted to the observed increased lipid peroxidation due to the elevated n-3 PUFA content of membrane phospholipids.

The evaluation of the global plasma antioxidant capacity of ZDF rats was significantly decreased despite the increase of the GPx enzyme activity even though specific activities of other antioxidant enzymes such as thioredoxin reductase or other peroxidases were not determined. This indicates an increased presence of ROS in their plasma as evidenced also by the disappearance of the plasma thiol groups, even though it did not reach absolute significance ($p = 0.079$, ANOVA). The observed hyperglycemia and hyperinsulinemia could have also induced the NADPH oxidase activity and the consequent production of H_2O_2 [45] that could explain the increased activity of GPx. The elevated activity of GPx may thus reflect a protective response against increased oxidative stress, since oxidative stress-induced antioxidant adaptive response could be particularly important in high ROS environments. Thus, an increased oxidative stress was already present in the

cardiac tissue and plasma at the early phase of T2D despite the effort of the organism (CIV and GPx activities) to eliminate it.

The development of T2D also induced changes in the fatty acid profile of cardiac membrane phospholipids that may influence lipid-protein interactions, inflammation and related metabolic processes. In particular, an increase in the SFAs in cardiac membranes was observed to the detriment of MUFAs. This increased degree of saturation could negatively affect the membrane fluidity and increase its rigidity. However, an increase in the PUFAs content, in particular the C20:4 n-6 (arachidonic acid, AA), C22:5 n-3 (docosapentaenoic acid, DPA) and C22:6 n-3 (docosahexaenoic acid, DHA) contents, was observed probably as an effort to maintain a proper membrane fluidity degree. Moreover, these increases seem to result from stimulation of the desaturation and elongation enzymes in the organism of the ZDF rats rather than from an increase in the concentration of the initial phospholipids of the PUFAs metabolisms (e.g. C18:2 n-6 and C20:5 n-3 for n-6 and n-3 respectively). It has been observed that tissues such as heart, kidney and liver from diabetic rats are characterized by a decrease in arachidonylated phospholipids and an increase in phospholipids containing linoleic acid (LA, C18:2 n-6). However, these modifications are mostly related to the later stages of diabetes. The n-3 and n-6 PUFAs of membrane phospholipids are also responsible for the production of anti- and pro-inflammatory molecules respectively. The low ratio EPA (eicosapentaenoic acid)/AA found in our ZDF rats predisposes to a balance of eicosanoids favouring platelet aggregation and inflammatory mediator signaling [46]. The development of a compensatory mechanism might thus be in question as the levels of n-3 PUFAs were increased in the ZDF group. Low levels of EPA + DHA have been related to increased risk for sudden cardiac death [46] and hearts with high DHA content present very low *in vivo* and *in vitro* vulnerability to arrhythmia [47]. The ZDF hearts have high levels of EPA + DHA in order to reduce pro-inflammatory eicosanoids and cytokines. These modifications in the PUFAs levels of the cardiac membrane phospholipids probably help the heart to resist to any sudden cardiac damage at this early phase of diabetes [47].

In our study, we reported a strong decrease in the *ex vivo* cardiac function as already shown in pre-diabetic [48] and diabetic [49,50] states, even though Daniels *et al.* [51] did not find an impaired *in vivo* cardiac function in db/db mice until 18 weeks of age. This could reflect the fact that in our study we have used an *ex vivo* heart perfusion model where the perfusion buffer is similar for both control and diabetic groups while the diabetic hearts *in vivo* are submitted to different plasma substrate and hormone concentrations than the control

ones. In our *ex vivo* model, the RPP was significantly reduced, mainly because of the decreased heart rate. The T2D-induced reduction of the heart rate has already been commonly shown in the diabetic state [52] and it has been explained by an abnormal functioning of the cells involved in the generation and transfer of the electric influx triggering the cardiac contraction [53]. We also observed a noticeable diabetes-induced decrease in the coronary flow. This decrease could also be responsible for the reduction of the heart rate and cardiac mechanical work through insufficient oxygen supply. This could not be explained by an increase in the vascular tone triggering vasoconstriction and limitation of the oxygen and substrate supply since no abnormalities of the vascular function were observed according to the results of the vascular reactivity. Finally, the two phenomena could be synergistic and lead to the decreased RPP. In contrast, the left ventricle developed pressure was increased, which could compensate for the decreased heart rate. This phenomenon could be related to the action of sarcoplasmic reticulum Ca^{2+} ATPase (SERCA) whose levels have been shown to be increased in early diabetes and especially stimulated by the presence of insulin [54] but were not evaluated in this work. Thus, our data confirm a decrease in the *ex vivo* cardiac function, and particularly in the heart rate, at this model of heart perfusion, which is a common characteristic of all types of diabetes.

The underlying mechanism, which could explain the observed decreased cardiac mechanical work, has been already characterized. Several metabolic modifications in our study suggest that the reduced *ex vivo* cardiac function was due to this mechanism. In this study, we found an increased plasma triglyceride concentration that could allow the excess free fatty acid uptake and stimulation of the peroxisome proliferator-activated receptor alpha (PPAR α) [50]. This would lead to increased β -oxidation and mitochondrial oxygen consumption [55]. The resulting excessive mitochondria-related ROS production, as evidenced by the aconitase-to-fumarase ratio in our study, would favour the expression of protein 53 (p53). The observed increased activity of the cytochrome c oxidase suggests an increased expression of the cytochrome c oxidase 2 (SCO2). Consequently, ectopic lipid accumulation may occur in the cardiomyocytes through increased expression of the fatty acid translocase protein FAT/CD36. Lipotoxicity then contributes to cardiac cell damages and myocardial dysfunction. A severe intramyocardial lipid accumulation, even at 8 wk of age [56] and an increased fatty acid oxidation [49] have been observed in ZDF rats. Thus, the altered myocardial substrate utilization affecting the mitochondrial function and stimulating the above described mechanism could be one of the factors responsible for the development of the T2D-

induced *ex vivo* cardiac mechanical dysfunction leading to reduction of oxygen demand and subsequent decrease in the coronary perfusion. In our study though we did not observe any decrease in the left ventricle developed pressure that could have resulted from this mechanism. Instead, the heart rate was the parameter mostly affected by the diabetes in our study. However, the conditions of the perfusion model did not allow us to evaluate correctly the left ventricle developed pressure. A future study of heart perfusion at stable heart rate (pacing) in order to evaluate the cardiac contractility and relaxation by measuring the maximal rate of the ventricular pressure rise (dP/dt_{max}) and fall (dP/dt_{min}) respectively could enlighten our knowledge concerning this mechanism. Taken together, these observations suggest that the lipid accumulation and alterations of substrate utilization in ZDF rats may affect firstly the cells responsible for the cardiac contraction that are involved in the generation and transfer of the electric influx. Furthermore, hyperglycemia and insulin resistance, two states that characterized the ZDF rats in this study, have been related to damages in cardiac nodal cells and to cardiac electrophysiological properties.

The effects of the T2D on the function of the coronary resistance arteries were also evaluated in this *ex vivo* model of isolated perfused heart through measurement of the coronary reactivity. This parameter was estimated through changes in the global coronary tone which mainly reflects the function of the arteriole network, since atherosclerosis does not occur in the rat [57]. The effects of T2D on the heart can thus be evaluated independently of the development of coronary artery disease. In this study, the EDD of diabetic hearts was fully maintained while the EID was even enhanced. We also evaluated indirectly the NO production through measurements of the expression and phosphorylation of the cardiac and aortic eNOS, since the phosphorylation of the enzyme at this site has been shown to increase NO production [58], and that of the iNOS levels, since it has been shown that under diabetic conditions stress-induced iNOS is able to produce an abnormal amount of NO [59]. In our study though, diabetes did not modify neither cardiac iNOS levels nor the expression and phosphorylation of eNOS at Ser1177, even though studies concerning other phosphorylation sites or the cGMP signaling pathway were not performed. It has been recently shown that the formation of superoxide from uncoupled bovine eNOS in endothelial cell can be stimulated by this kind of phosphorylation [60]. The presence of increased oxidative stress in the diabetic hearts of the ZDF rats could have led to the depletion of tetrahydrobiopterin (BH_4) and uncoupling of the eNOS. This could result to increased production of ROS from the enzyme even though there was no change in the phosphorylation of eNOS at Ser1177. The consequent

superoxide production could lead to H_2O_2 production, which could have participated to the maintained EDD of our study since it has been shown that this molecule can act as endothelium-hyperpolarizing factor (EDHF) [61]. The maintained EDD was a surprising finding given the huge amount of studies associating T2D and dysfunctions of the coronary microcirculation [62-64]. Factors contributing to these discrepancies are the severity of the obesity and diabetic state studied as well as the experimental method used. Oltman *et al.* [22] have reported a preservation of the coronary arteriolar dilatation to Ach in isolated vessels of pre-diabetic young (8- to 12-wk old) ZDF rats. However, in the present study, the ZDF rats were not in a prediabetic state, but the T2D was already developed as indicated by the blood glucose concentration, which was already high from the 8th wk of age. Thus, it seems that the endothelial function of the intact coronary microvasculature is not affected from the diabetes at this phase. The unaltered eNOS and iNOS activities and the high levels of AA and DHA despite the presence of oxidative stress found in the diabetic hearts could have contributed to this phenomenon. AA [65] and DHA [66] are known for their vasorelaxant effects via the production of prostacyclin (PGI₂) and the reduction of calcium influx in vascular smooth muscle cells. A future study of vascular reactivity in the presence of a cyclo-oxygenase (COX) inhibitor such as indomethacin could enlighten this hypothesis. Furthermore, the early diabetes could have provoked an increased expression of SERCA [54] favouring the calcium uptake in vascular smooth muscle cells that could be involved in the increased EID observed in the ZDF diabetic hearts of this study.

As shown by the calculated activity of endothelial cells to induce dilatation and the evaluation of eNOS expression the phenomenon of the maintained Ach-mediated vasodilatation was partly mediated by the activity of endothelial cells. However, the SNP responses were enhanced in the ZDF rats representing an enhanced function of the smooth muscle cells of the coronary system contributing to the maintained endothelium-dependent dilatation. This enhanced function may be due to a modified NO response, which could increase guanylate cyclase activity as already shown in cases of obesity and hypertension [67,68].

These vascular alterations may reflect a compensatory adaptation of the cardiovascular system to support increased cardiac work since cardiac output and stroke volume are increased in obese and diabetic states [69,70]. Taken also under consideration the decreased *ex vivo* cardiac mechanical function observed in this study, this adaptation seems to be essential to adjust organ perfusion during physiological processes such as exercise and pathological processes such as ischemic

diseases [11]. Otherwise, the heart would not be able to respond to the increased metabolic demands. These results come in agreement with data of Oltman *et. al* [22] that showed that there is no change in the Ach response of small coronary arteries in ZDF rats at the age of 8–12 weeks but there is a progressive impairment until the age of 40 weeks.

Conclusions

Cardiovascular function was evaluated in young diabetic ZDF rats using an *ex vivo* heart perfusion model. Our data suggest that at the early phase of diabetes, increased oxidative stress in tissue and plasma is already present and probably responsible for the observed *ex vivo* cardiac mechanical dysfunction. However, the heart tries to resist by preserving the EDD of the coronary microvasculature. A number of other adaptations seem to take place at this phase of the disease such as the increased GPx and CIV activities and the increase in the n-3 PUFAs content of the myocardial membrane. This would help the heart to keep an adequate perfusion and respond to any acute cardiac incident at this phase. Thus, therapeutic interventions at this early phase of the disease aiming at increasing the heart rate and maintaining the observed adaptations could be an option for delaying or decreasing the late-stage complications of the diabetes.

Submit your next manuscript to BioMed Central and take full advantage of:

- Convenient online submission
- Thorough peer review
- No space constraints or color figure charges
- Immediate publication on acceptance
- Inclusion in PubMed, CAS, Scopus and Google Scholar
- Research which is freely available for redistribution

Submit your manuscript at
